1 Introduction

This program is designed to improve the estimation of causal effects via a powerful method of matching that is widely applicable in observational data and exceptionally easy to understand and use (if you understand how to draw a histogram, you will understand this method). The program implements the CEM (Coarsened Exact Matching) algorithm. This algorithm, and its many attractive statistical properties, are described in

Stefano M. Iacus, Gary King, and Giuseppe Porro, "Matching for Causal Inference Without Balance Checking", http://gking.harvard.edu/files/abs/cem-abs.shtml.

The paper shows that CEM is a monotonoic imbalance bounding (MIB) matching method — which means that the maximum imbalance between the treated and control groups is chosen by the user ex ante rather than discovered through the usual laborious process of checking after the fact and repeatedly reestimating, and so that adjusting the imbalance on one variable has no effect on the maximum imbalance of any other. CEM also strictly bounds through ex ante user choice both the degree of model dependence and the average treatment effect estimation error, eliminates the need for a separate procedure to restrict data to common empirical support, meets the congruence principle, is robust to measurement error, works well with multiple imputation and other methods for missing data, can be completely automated, and is extremely fast computationally even with very large data sets. After preprocessing data with CEM, the analyst may then use a simple difference in means or whatever statistical model they would have applied without matching. CEM also works well for multicategory treatments, creating randomized blocks in experimental designs, and evaluating extreme counterfactuals.

2 Setup

2.1 Software Requirements

CEM works in conjunction with the R Project for Statistical Computing, and will run on any platform where R is installed (Windows, Linux, or Mac). R is available free for download at the Comprehensive R Archive Network (CRAN) at http://cran.r-project.org/. CEM has been tested on the most recent version of R.

CEM may be run by installing the program directly, as indicated below, or by using the alternative interface to CEM provided by MatchIt (http://gking.harvard.edu/matchit, (Ho et al., Forthcoming)). Using CEM directly is faster. The MatchIt interface is easier for some applications and works seemlessly with Zelig (http://gking.harvard.edu/zelig)

for estimating causal effects after matching, but presently only offers a subset of features of the R version. A Stata version of CEM is also available at the CEM web site, http://gking.harvard.edu/cem.

2.2 Installation

To install cem, type at the R command prompt,

> install.packages("cem")

and CEM will install itself onto your system automatically from CRAN. You may alternatively load the beta test version as

> install.packages("cem",repos="http://gking.harvard.edu/cem")

2.3 Loading CEM

You need to install CEM only once, but you must load it prior to each use. Do this at the R prompt:

> library(cem)

2.4 Updating CEM

We recommend that you periodically update CEM at the R prompt by typing:

> update.packages()

which will update all the libraries including CEM and load the new version of the package with

> library(cem)

3 A User's Guide

We show here how to use CEM through a simple running example: the National Supported Work (NSW) Demonstration data, also known as the Lalonde data set (Lalonde, 1986). This program provided training to selected individuals for 12-18 months and help finding a job in the hopes of increasing their' earnings. The treatment variable, treated, is 1 for participants (the treatment group) and 0 for nonparticipants (the control group). The key outcome variable is earnings in 1978 (re78). The statistical goal is to estimate a specific version of a causal effect: the sample average treatment effect on the treated (the "SATT").

Since participation in the program was not assigned strictly at random, we must control for a set of pretreatment variables by the CEM algorithm. These pre-treatment variables include age (age), years of education (education), marital status (married), lack of a high

school diploma (nodegree), race (black, hispanic), indicator variables for unemployment in 1974 (u74) and 1975 (u75), and real earnings in 1974 (re74) and 1975 (re75). Some of these are dichotomous (married, nodegree, black, hispanic, u74, u75), some are categorical (age and education), and the earnings variables are continuous and highly skewed with point masses at zero. We modify these data by adding a (fictitious) variable to illustrate discrete responses called q1, the answer to a survey question asking before assignment for an opinion about this job training program, with possible responses strongly agree, agree, neutral, strongly disagree, disagree, and no opinion; note that the last category is not on the same ordered scale as the other responses. Ten percent of the observations have missing data (added randomly by us to illustrate how CEM deals with missingness). We call this new data set the LeLonde (intentionally misspelling Lalonde); the original, unmodified Lalonde (1986) data are contained in data set LL.

Matching is not a method of estimation; it is a way to preprocess a data set so that estimation of SATT based on the matched data set will be less "model-dependent" (i.e., less a function of apparently small and indefensible modeling decisions) than when based on the original full data set. Matching involves pruning observations that have no close matches on pre-treatment covariates in both the treated and control groups. The result is typically less model-dependence, bias, and (by removing heterogeneity) inefficiency (King and Zeng, 2006; Ho et al., 2007; Iacus, King and Porro, 2008).

3.1 Basic Evaluation and Analysis of Unmatched Data

We begin with a naive estimate of SATT — the simple difference in means — which would be useful only if the in-sample distribution of pre-treatment covariates were the same in the treatment and control groups:

```
> require(cem)
How to use CEM? Type vignette("cem")
> data(LeLonde)
```

We remove missing data from the data set before starting the analysis (we show better procedures for dealing with missing data in Section 3.6).

```
> Le <- data.frame(na.omit(LeLonde))
```

and then compute the size of the treated and control groups:

```
> tr <- which(Le$treated == 1)
> ct <- which(Le$treated == 0)
> ntr <- length(tr)
> nct <- length(ct)</pre>
```

Thus, the data include 258 treated units and 392 control units. The (unadjusted and therefore likely biased) difference in means is then:

```
> mean(Le$re78[tr]) - mean(Le$re78[ct])
```

[1] 759

Because the variable treated was not randomly assigned, the pre-treatment covariates differ between the treated and control groups. To see this, we focus on these pre-treatment covariates:

The overall imbalance is given by the \mathcal{L}_1 statistic, introduced in Iacus, King and Porro (2008) as a comprehensive measure of global imbalance. It is based on the L_1 difference between the multidimensional histogram of all pretreatment covariates in the treated group and that in the control group. Perfect global balance is indicated by $\mathcal{L}_1 = 0$, and larger values indicate larger imbalance between the groups. To use this measure, we require a list of bin sizes for the numerical variables. Our functions compute these automatically, or they can be set by the user.¹

We compute \mathcal{L}_1 statistic, as well as several unidimensional measures of imbalance via our imbalance function. In our running example:

> imbalance(group = Le\$treated, data = Le[vars])

Multivariate Imbalance Measure: L1=1.600657

Univariate Imbalance Measures:

	statistic	type	L1	${\tt min}$	25%	50%	75%	max
age	-0.252373	(diff)	0.16160	0	0	0.0	-1.0	-6.0
${\tt education}$	0.153635	(diff)	0.22243	1	0	1.0	1.0	1.0
black	-0.010323	(diff)	0.02065	0	0	0.0	0.0	0.0
married	-0.009551	(diff)	0.01910	0	0	0.0	0.0	0.0
nodegree	-0.081217	(diff)	0.16243	0	-1	0.0	0.0	0.0
re74	-18.160447	(diff)	0.08630	0	0	284.1	806.3	-2139.0
re75	101.501762	(diff)	0.13475	0	0	485.6	1238.4	490.4
hispanic	-0.010145	(diff)	0.02029	0	0	0.0	0.0	0.0
u74	-0.045582	(diff)	0.09116	0	0	0.0	0.0	0.0
u75	-0.065555	(diff)	0.13111	0	0	0.0	0.0	0.0
q1	7.494021	(Chi2)	0.21342	NA	NA	NA	NA	NA

¹Of course, as with drawing histograms, the choice of bins affects the final result. The important thing is to choose one and keep it the same throughout to allow for fair comparisons. The particular choice is less crucial.

Only the overall \mathcal{L}_1 statistic measure includes imbalance with respect to the full joint distribution, including all interactions, of the covariates; in the case of our example, $\mathcal{L}_1 = 1.601$. The unidimensional measures in the table are all computed for each variable separately.

The first column in the table of unidimensional measures, labeled statistic, reports the difference in means for numerical variables (indicated by the second column, type, reporting (diff)) or a chi-square difference for categorical variables (when the second column reports (Chi2)). The second column, labeled L1, reports the \mathcal{L}_1^j measure, which is \mathcal{L}_1 computed for the j-th variable separately (which of course does not include interactions). The remaining columns in the table report the difference in the empirical quantile of the distributions of the two groups for the 0th (min), 25th, 50th, 75th, and 100th (max) percentiles for each variable. When the variable type is Chi2, the only variable-by-variable measure that is defined in this table is \mathcal{L}_1^j ; others are reported missing.

This particular table shows that variables re74 and re75 are imbalanced in the raw data in many ways and variable age is balanced in means but not in the quantiles of the two distributions. This table also illustrates the point that balancing only the means between the treated and control groups does not necessarily guarantee balance in the rest of the distribution. Most important, of course, is the overall \mathcal{L}_1 measure, since even if the marginal distribution of every variable is perfectly balanced, the joint distribution can still be highly imbalanced.

As an aside, we note that for convenience that the function **imbalance** allows you to drop some variables before computation:

```
todrop <- c("treated", "re78")
imbalance(group=Le$treated, data=Le, drop=todrop)</pre>
```

3.2 Coarsened Exact Matching

We now apply the coarsened exact matching algorithm by calling the function cem. The CEM algorithm performs exact matching on coarsened data to determine matches and then passes on the uncoarsened data from observations that were matched to estimate the causal effect. Exact matching works by first sorting all the observations into strata, each of which has identical values for all the coarsened pre-treatment covariates, and then discarding all observations within any stratum that does not have at least one observation for each unique value of the treatment variable.

To run this algorithm, we must choose a type of coarsening for each covariate. We show how this is done this via a fully automated procedures in Section 3.2.1. Then we show how to use explicit prior knowledge to choose the coarsening in Section 3.2.2, which is normally preferable when feasible.

In CEM, the treatment variable may be dichotomous or mutichotomous. Alternatively, cem may be used for randomized block experiments without specifying a treatment variable; in this case no strata are deleted and the treatment variable is (randomly) assigned to units within each strata to ensure that each has at least one observation assigned each value of the treated variable.

3.2.1 Automated Coarsening

In our running example we have a dichotomous treatment variable. In the following code, we match on all variables but re78, which is the outcome variable and so should never be included. Hence we proceed specifying "re78" in argument drop:

```
> mat <- cem(treatment = "treated", data = Le, drop = "re78")
```

The output object mat contains useful information about the match, including a (small) table about the number of observations in total, matched, and unmatched, as well as the results of a call to the imbalance function for information about the quality of the matched data (unless eval.imbalance is set to FALSE). Since cem bounds the imbalance ex ante, the most important information in mat is the number of observations matched. But the results also give the imbalance in the matched data using the same measures as that in the original data described in Section 3.1. Thus,

> mat

	GO	G1
All	392	258
Matched	95	84
Unmatched	297	174

Multivariate Imbalance Measure: L1=1.378175

Univariate Imbalance Measures:

	statistic	type	L1	min	25%	50%	75%	max
age	9.405e-02	(diff)	1.615e-01	0	0	1.0	0.0	0.0
education	-2.222e-02	(diff)	4.444e-02	0	0	0.0	0.0	0.0
black	1.110e-16	(diff)	1.110e-16	0	0	0.0	0.0	0.0
married	0.000e+00	(diff)	0.000e+00	0	0	0.0	0.0	0.0
nodegree	0.000e+00	(diff)	1.388e-17	0	0	0.0	0.0	0.0
re74	1.496e+02	(diff)	1.913e-01	0	0	0.0	463.3	889.5
re75	1.588e+02	(diff)	2.782e-01	0	0	165.2	843.7	-640.9
hispanic	0.000e+00	(diff)	0.000e+00	0	0	0.0	0.0	0.0
u74	0.000e+00	(diff)	0.000e+00	0	0	0.0	0.0	0.0
u75	0.000e+00	(diff)	0.000e+00	0	0	1.0	0.0	0.0
q1	2.083e+00	(Chi2)	2.776e-17	NA	NA	NA	NA	NA

We can see from these results the number of observations matched and thus retained, as well as those which were pruned because they were not comparable. By comparing the imbalance results to the original imbalance table given in the previous section, we can see that a good match can produce a substantial reduction in imbalance, not only in the means, but also in the marginal and joint distributions of the data.

The function cem also generates weights for use in the evaluation of imbalance measures and estimates of the causal effect (stored in mat\$w).

3.2.2 Coarsening by Explicit User Choice

The power and simplicity of CEM comes from choosing the coarsening yourself rather than using the automated algorithm as in the previous section. Choosing the coarsening enables you to set the maximum level of imbalance ex ante, which is a direct function of the coarsening you choose. By controlling the coarsening, you also put an explicit bound on the degree of model dependence and the SATT estimation error.

Fortunately, the coarsening is a fundamentally substantive act, almost synonymous with the measurement of the original variables. In other words, if you know something about the data you are analyzing, you almost surely have enough information to choose the coarsening. (And if you don't know something about the data, you might ask why you are analyzing it in the first place!)

In general, we want to set the coarsening for each variable so that substantively indistinguishable values are grouped and assigned the same numerical value. Groups may be of different sizes if appropriate. Recall that any coarsening during CEM is used only for matching; the original values of the variables are passed on to the analysis stage for all matched observations.

The function cem treats categorical and numerical variables differently.

For *categorical* variables, we use the **grouping** option. For example, in variable **q1** may want to set this option such that we form three separate groups like this:

```
> q1.grp <- list(c("strongly agree", "agree"), c("neutral", "no opinion"),
+ c("strongly disagree", "disagree"))</pre>
```

For *numerical* variables, we use the **cutpoints** option. Thus, for example, in the US educational system, the following discretization of years of education corresponds to different levels of school

Grade school 0–6
Middle school 7–8
High school 9–12
College 13–16
Graduate school >16

Using these natural breaks in the data to create the coarsening is generally a good approach and certainly better than using fixed bin sizes (as in caliper matching) that disregard these meaningful breaks. Because in our data, no respondents fall in the last category,

> table(Le\$education)

we define the cutpoints as:

```
> educut <- c(0, 6.5, 8.5, 12.5, 17)
```

and run cem adding only the grouping and cutpoints options, leaving the rest unchanged:

- > mat1 <- cem(treatment = "treated", data = Le, drop = "re78",
 + cutpoints = list(education = educut), grouping = list(q1.grp))
 > mat1
- G0 G1
 All 392 258
 Matched 137 91
 Unmatched 255 167

Multivariate Imbalance Measure: L1=1.502359

Univariate Imbalance Measures:

	statistic	type	L1	${\tt min}$	25%	50%	75%	max
age	1.809e-01	(diff)	2.974e-01	0	0	1	0.0	0.0
education	5.716e-02	(diff)	8.716e-02	0	1	0	0.0	-2.0
black	0.000e+00	(diff)	0.000e+00	0	0	0	0.0	0.0
married	0.000e+00	(diff)	1.110e-16	0	0	0	0.0	0.0
nodegree	0.000e+00	(diff)	1.388e-17	0	0	0	0.0	0.0
re74	1.022e+02	(diff)	1.522e-01	0	0	0	463.3	889.5
re75	1.161e+02	(diff)	2.562e-01	0	0	0	843.7	-640.9
hispanic	-6.939e-18	(diff)	6.939e-18	0	0	0	0.0	0.0
u74	0.000e+00	(diff)	0.000e+00	0	0	0	0.0	0.0
u75	-1.110e-16	(diff)	1.665e-16	0	0	0	0.0	0.0
q1	2.064e+00	(Chi2)	6.939e-17	NA	NA	NA	NA	NA

As we can see, this matching solution differs from that resulting from our automated approach in the previous section. For comparison, the automatic cutpoints produced by cem are stored in the output object in slot breaks. So, for example, our automated coarsening produced:

> mat\$breaks\$education

whereas we can recover our personal choice of cutpoints as

> mat1\$breaks\$education

[1] 0.0 6.5 8.5 12.5 17.0

3.3 Progressive coarsening

Although the maximum imbalance is fixed ex ante by the user's coarsening choices, the number of observations matched is determined as a consequence of the matching procedure. If you are dissatisfied with the number of observations available after matching, and you feel that it is substantively appropriate to coarsen further, then just increase the coarsening (by using fewer cutpoints). The result will be additional matches and of course a concommitant increase in the maximum possible imbalance between the treated and control groups. This is easy with CEM because, unlike most other methods, CEM is a monotonic imbalance bounding (MIB) method, which means that increasing the imbalance on one variable (through a change in coarsening) will not change the maximum imbalance on any other variable. MIB thus enables you to tinker with the solution one variable at a time to quickly produce a satisfactory result, if one is feasible.

If, however, you feel that additional coarsening is not appropriate, than too few obserations may indicate that your data contains insufficient information to estimate the causal effects of interest without model dependence; in that situation, you either give up or will have to attempt adjusting for the pre-treatment covariates via modeling assumptions.

Suppose, instead, that you are unsure whether to coarsen further or how much to coarsen, and are willing to entertain alternative matching solutions. We offer here an automated way to compute these solutions. The idea is to relax the initial cem solution selectively and automatically, to prune equivalent solutions, and to present them in a convenient manner so that users can ascertain where the difficulties in matching in these data can be found and what choices would produce which outcomes in terms of the numbers of observations matched.

We start by illustrating what happens when we relax a CEM solution "by hand". The following three runs show the effect on the matching solution (in terms of the number of observations and imbalance) when the coarsening for one variable (age) is relaxed from 10 to 6 to 3 bins. As can be seen, fewer cutpoints (which means larger bins) produces more matched units and high maximum (and in this case actual) imbalance:

Multivariate Imbalance Measure: L1=1.276190

We automate this *progressive coarsening* procedure here in the relax.cem function. This function starts with the output of cem and relaxes variables one (depth=1), two (depth=2), or three (depth=3) at a time, while optionally keeping unchanged a chosen subset of the variables which we know well or have important effects on the outcome (fixed). The function also allows one to specify the minimal number of breaks of each variable (the default limit being 1). We begin with this example (the argument perc=0.3 is passed to the plot function and implies that only the solutions with at least 30% of the units are matched)

```
> tab <- relax.cem(mat, Le, depth = 1, perc = 0.3)

Executing 47 different relaxations
......[20%]....[40%].....[60%].....[80%].....[100%]
```

After all possible coarsening relaxations are attempted, the function returns a list of tables, one per group (i.e. treated and control). Each row of the tables contain information about the number of treated and control units matched, the value of the \mathcal{L}_1 measure, and the type of relaxation made. Each table is the sorted according to the number of treated (or control) units matched.

The user may want to see the output of tab\$G1 or tab\$G0 but these tables may be very long, and so we provide a method plot to view these tables more conveniently. The output of plot(tab) is plotted in Figure 1 from which it is seen that the most difficult variables to match are age and education. On the x-axis of the plot the variable and the number of

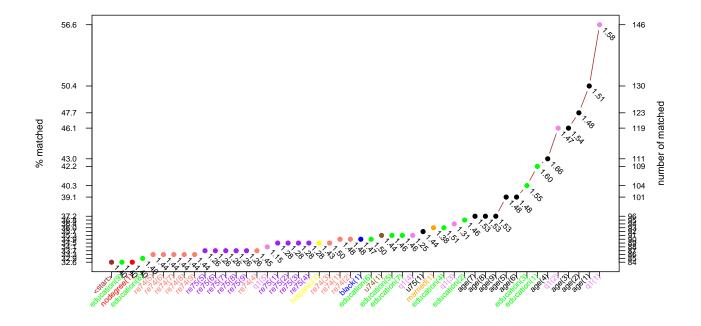

Figure 1: Example of the graphical output of relax.cem.

equally sized bins used for the coarsening are used (color-coded by variable). On the y-axis on the right is the absolute number of treated units matched, while the left side y-axis reports the same number in percentages. The numbers below the dots in the graphs represent the \mathcal{L}_1 measure corresponding to that matching solution. This graph also gives a feeling of the MIB behaviour of cem. When the tables produced by relax.cem are too large, the plot function, allows for some reduction like printing only the best matching solutions (in the terms of number of treated units matched), removing duplicates (i.e. different coarsenings may lead to the same matching solution), or printing only solution where at least some percentage of treated units, have been matched, or a combination of these. For more information refer to the reference manual for the function relax.plot which can be called directly instead of plot.

Here is one example of use of plot in which we specify that only solutions with at least 60% of the treated units are matched and duplicated solutions are removed. The output can be seen in Figure 2

> plot(tab, group = "1", perc = 0.35, unique = TRUE)

3.4 Restricting the matching solution to a k-to-k match

By default, CEM uses maximal information, resulting in strata that may include different numbers of treated and control units. To compensate for the differential strata sizes, cem also

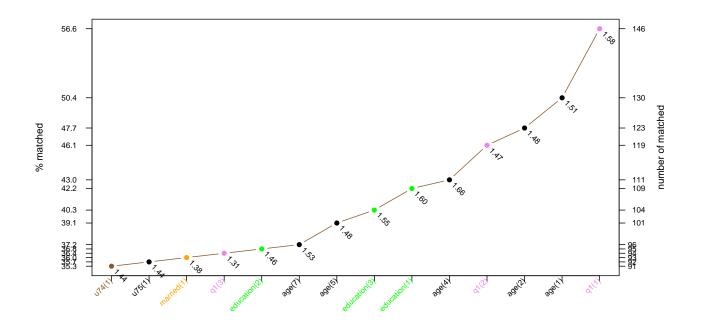

Figure 2: Example of reduced graphical output of relax.cem.

returns weights to be used in subsequent analyses. Although this is generally the best option, a user with enough data may opt for a k-to-k solution to avoid the slight inconvenience of needing to use weights.

The function k2k accomplishes this by pruning observations from a cem solution within each stratum until the solution contains the same number of treated and control units in all strata. Pruning occurs within a stratum (for which observations are indistuinguishable to cem proper) by using nearest neighbor selection using a distance function specified by the user (including euclidean, maximum, manhattan, canberra, binary, or minkowski). By default method is set to NULL, which means random matching inside cem strata, an option that may reduce the chance for bias. (For the Minkowski distance the power can be specified via the argument mpower. For more information on method != NULL, refer to dist help page.)

Here is an example of this approach. First, by running cem:

Multivariate Imbalance Measure: L1=1.378175

```

> mat2\$k2k

[1] TRUE

Alternatively, we can produce the same result in one step by adding the k2k=TRUE option to the original cem call.

3.5 Estimating the Causal Effect from cem output

Using the output from cem, we can estimate SATT via the att function. The simplest approach requires a weighted difference in means (unless k2k was used, in which case no weights are required). For convenience, we compute this as a regression of the outcome variable on a constant and the treatment variable,

```
> est <- att(mat, re78 ~ treated, data = Le)
> est
```

	(Intercept)	treated
Estimate	3.844e+03	1159.2542
Std. Error	5.729e+02	836.3207
t value	6.710e+00	1.3861
Pr(> t)	2.541e-10	0.1674

where the SATT estimate is the coefficient on the treated variable, in our case 1159.25. The function att allows for R's standard formula interface and, by default, uses 1m to estimate the model using the weights produced by cem.

If exact matching (i.e., without coarsening) was chosen this procedure is appropriate as is. In other situations, with some coarsening, some imbalance remains in the matched data. The remaining imbalance is strictly bounded by the level of coarsening, which can be seen by any remaining variation within the coarsened bins. Thus, a reasonable approach in this common situation is to attempt to adjust for the remaining imbalance via a statistical model. (Modeling assumptions for models applied to the matched data are much less consequential than they would otherwise be because CEM is known to strictly bound the level of model dependence.) To apply a statistical model to control for the remaining imbalance, we use the formula interface in att. For example:

```
> est2 <- att(mat, re78 ~ treated + re74 + re75, data = Le)
> est2
```

```
(Intercept)
                          treated
                                     re74
                                             re75
Estimate
             3.862e+03 1161.6711 -0.2480 0.2490
Std. Error
             6.370e+02
                         841.5957
                                   0.8338 0.8785
t value
             6.062e+00
                           1.3803 -0.2974 0.2834
Pr(>|t|)
             8.035e-09
                           0.1692
                                   0.7665 0.7772
```

The user can also specify glm modeling in the case of binary, count, or other noncontinuous outcome variables. For more information, see the reference manual entry for att.

3.6 Matching and Missing Data

Almost all previous methods of matching assume the absence of any missing values. In contrast, CEM offers two valid approaches to dealing with missing values (item nonresponse). In the first, where we treat missing values as one of the values of the variables, is appropriate when "NA" is a valid value that is not really missing (such as when "no opinion" really means no opinion); see Section 3.6.1. The other is a special procedure to allow for multiply imputed data in CEM, as described in Section 3.6.2.

3.6.1 Matching on Missingness

In the next example, we use our original LeLonde data with missing values and we compare the result with Le from which we dropped the NA values. For comparability, we use the same cutpoints we used in Section 3.2 on the Le data. The cutpoints are contained in mat\$breaks

```
> mat3 <- cem("treated", LeLonde, drop = "re78", cutpoints = mat$breaks,
+ grouping = list(q1 = q1.grp))</pre>
```

Missing values exist in the data!

and, as expected, the two solutions differ somewhat. The gain (in terms of number of matched units) decreases as the number of covariates increases.

3.6.2 Matching Multiply Imputed Data

Consider a data set to be matched, some of which is missing. One approach to analyzing data with missing values is *multiple imputation*, which involves creating m (usually about m=5) data sets, each of which is the same as the original except that the missing values have been imputed in each. Uncertainty in the values of the missing cells is represented by variation in the imputations across the different imputed data sets (King et al., 2001).

As an example we take the original LeLonde data with missing values

> summary(LeLonde)

                                                                            5
```

Now we use Amelia package (Honaker, King and Blackwell, 2006) to create multiply imputed data sets:

```
-- Imputation 1 --

1 2 3
-- Imputation 2 --

1 2 3 4
-- Imputation 3 --

1 2 3
-- Imputation 4 --

1 2 3 4
-- Imputation 5 --

1 2 3
```

Now imputed contains a list of 5 multiply imputed versions of LeLonde. We pass this list to the cem function in the argument datalist and cem produces a set of multiply imputed solutions, as usual with the original uncoarsened values of the variables, but now assigning each multiply imputed observation to the strata where it falls most frequently. The output of cem is a list of cem.match solutions (named match1, match2,..., match5). (Be sure to also name the original data frame in option data or cem will merely run the basic algorithm five separate times on each of the input data sets, a procedure that can be useful for batch processing of data to be matched, but is not recommended for multiply imputed data sets since the strata will not be the same across the data sets.) For example:

Multivariate Imbalance Measure: L1=1.449320

Univariate Imbalance Measures:

Unmatched 293 199

	statistic	type	L1	min	25%	50%	75%	max
age	-1.419e-01	(diff)	1.969e-01	0.0	-1	0	0.0	0.0
${\tt education}$	-3.269e-03	(diff)	1.361e-02	0.0	0	0	0.0	0.0

u74	4.082e-03	(diff)	4.082e-02	0.0	0	0	0.0	0.0
u75	1.110e-16	(diff)	1.110e-16	0.0	0	0	0.0	0.0
q1	2.141e+00	(Chi2)	1.238e-01	NA	NA	NA	NA	NA

Now we estimate SATT via the usual multiple imputation combining formulas (averaging the point estimates and within and between variances, as usual; see King et al. 2001). The function att implements these procedures:

> out <- att(mat2, re78 ~ treated, data = imputed)</pre>

4 Reference to CEM's Functions

4.1 cem: Coarsened Exact Matching

Description

Implementation of Coarsened Exact Matching

Usage

```
cem(treatment=NULL, data = NULL, datalist=NULL, cutpoints = NULL,
    grouping = NULL, drop=NULL, eval.imbalance = TRUE, k2k=FALSE,
    method=NULL, mpower=2, L1.breaks = NULL, verbose = 0)
```

Arguments

treatment character, name of the treatment variable

data a data.frame

datalist a list of optional multiply imputed data.frame's

cutpoints named list each describing the cutpoints for numerical variables (the

names are variable names). Each list element is either a vector of cutpoints, a number of cutpoints, or a method for automatic bin contruction.

See Details.

grouping named list, each element of which is a list of groupings for a single cate-

gorical variable. See Details.

drop a vector of variable names in the data frame to ignore during matching

eval.imbalance

Boolean. See Details.

k2k boolean, restrict to k-to-k matching? Default = FALSE

method distance method to use in k2k matching. See Details.

mpower power of the Minkowski distance. See Details.

L1.breaks list of cutpoints for the calculation of the L1 measure.

verbose controls level of verbosity. Default=0.

Details

When specifying cutpoints, several automatic methods may be chosen, including "sturges" (Sturges' rule, the default), "fd" (Freedman-Diaconis' rule), "scott" (Scott's rule) and "ss" (Shimazaki-Shinomoto's rule). See references for a description of each rule.

The grouping option is a list where each element is itself a list. For example, suppose for variable quest1 you have the following possible levels "no answer", NA, "negative", "neutral", "positive" and you want to collect ("no answer", NA, "neutral") into a single group, then the grouping argument should contain list(quest1=list(c("no

answer", NA, "neutral"))). Or if you have a discrete variable elements with values 1:10 and you want to collect it into groups "1:3,NA", "4", "5:9", "10" you specify in grouping the following list list(elements=list(c(1:3,NA), 5:9)). Values not defined in the grouping are left as they are. If cutpoints and groupings are defined for the same variable, the groupings take precedence and the corresponding cutpoints are set to NULL.

verbose: a number greater or equal to 0. The higher, the more info are provided during the execution of the algorithm.

If eval.imbalance = TRUE (the default), cem\$imbalance contains the imbalance measure by absolute difference in means for numerical variables and chi-square distance for categorical variables. If FALSE then cem\$imbalance is set to NULL. If data contains missing data, the imbalance measures are not calculated.

If L1.breaks is missing, the default rule to calculate cutpoints is the Scott's rule.

If k2k is set to TRUE, the algorithm return strata with the same number of treated and control units per stratum, otherwise all the matched units are returned (default). When k2k = TRUE, the user can choose a method (between 'euclidean', 'maximum', 'manhattan', 'canberra', 'binary' and 'minkowski') for nearest neighbor matching inside each cem strata. By default method is set to 'NULL', which means random matching inside cem strata. For the Minkowski distance the power can be specified via the argument mpower'. For more information on method != NULL, refer to dist help page.

By default, cem treats missing values as distinct categories and matches observations with missing values in the same variable in the same stratum provided that all the remaining (corasened) covariates match.

If argument data is non-NULL and datalist is NULL, CEM is applied to the single data set in data.

Argument datalist is a list of (multiply imputed) data frames (i.e., with missing cell values imputed). If data is NULL, the function cem is applied independently to each element of the list, resulting in separately matched data sets with different numbers of treated and control units.

When data and datalist are both non-NULL, each multiply imputed observation is assigned to the stratum in which it has been matched most frequently. In this case, the algorithm outputs the same matching solution for each multiply imputed data set (i.e., an observation, and the number of treated and control units matched, in one data set has the same meaning in all, and is the same for all)

Value

Returns an object of class cem.match if only data is not NULL or an object of class multicem, which is a list of objects of class cem.match plus a field called unique which is true only if data and datalist are not both NULL. A cem.match object is a list with the following slots:

call the call

strata vector of stratum number in which each observation belongs, NA if the

observation has not been matched

n.strata number of strata generated

vars report variables names used for the match

drop variables removed from the match

breaks named list of cutpoints, eventually NULL

treatment name of the treatment variable

groups factor, each observation belong to one group generated by the treatment

variable

n.groups number of groups identified by the treatment variable

group.idx named list, index of observations belonging to each group

group.len sizes of groups

tab summary table of matched by group

imbalance NULL or a vector of imbalances. See Details.

4.2 att: Example of ATT estimation from CEM output

Description

An example of ATT estimation from CEM output

Usage

```
att(obj, formula, data, model="lm", family="binomial")
```

Arguments

obj a cem.atch or multicem object

data a single data frame or a list of data frame's in case of multicem

formula type specification of model. See Details.

model either lm or glm. See Details.

family used if model is glm, otherwise ignored.

Details

Argument data must be a single data frame or a list of (mulitply imputed) data frames.

Argument model can be 1m or g1m if the outcome variable in the ATT estimation is, e.g., a binary outcome. If the outcome is y and the treatment variable is T, then a formula like y ~ T is enough to estimate the ATT: it is just the coefficient of T. User can add covariates to span any remaining imbalance after the match, such as y ~ T + age + sex, to adjust for variables age and sex.

In the case of multiply imputed datasets, the model is applied to each single matched data and the ATT and is the standard error estimated using the standard formulas for combining results of multiply imputed data.

Value

A matrix of estimates with their standard error, or a list in the case of multicem.

4.3 DW: Dehejia-Wahba dataset

Description

A subset of the Lalonde dataset (see cited reference).

Usage

data(DW)

Format

A data frame with 445 observations on the following 10 variables.

treated treated variable indicator

age age

education years of education

black race indicator variable

married marital status indicator variable

nodegree indicator variable of not possessing a degree

re74 real earnings in 1974

re75 real earnings in 1975

re78 real earnings in 1978 (post treatment outcome)

hispanic ethnic indicator variable

u74 unemployment in 1974 indicator variable

u75 unemployment in 1975 indicator variable

Source

see references

4.4 imbalance: Calculates several imbalance measures

Description

Calculates several imbalance measures for the original and matched data sets

Usage

```
imbalance(group, data, drop=NULL, breaks = NULL, weights)
```

Arguments

group the group variable

data the data

drop a vector of variable names in the data frame to ignore

breaks a list of vectors of cutpoints used to calculate the L1 measure. See Details.

weights weights

Details

This function calculates several imbalance measures. For numeric variables, the difference in means (under the column statistic), the difference in quantiles and the L1 measure is calculated. For categorical variables the L1 measure and the Chi-squared distance (under column statistic) is calculated. Column type reports either (diff) or (Chi2) to indicate the type of statistic being calculated.

If breaks is not specified, the Scott automated bin calculation is used (which coarsens less than Sturges, which used in cem). Please refer to cem help page. In this case, breaks are used to calculate the L1 measure.

This function also calculate the global L1 imbalance measure. If breaks is missing, the default rule to calculate cutpoints is the Scott's rule. See L1.meas help page for details.

Value

An object of class imbalance which is a list with the following two elements

tab Table of imbalance measures

L1 The global L1 measure of imbalance

Author(s)

Stefano Iacus, Gary King, and Giuseppe Porro

References

Stefano Iacus, Gary King, Giuseppe Porro, "Matching for Casual Inference Without Balance Checking," http://gking.harvard.edu/files/abs/cem-abs.shtml

Examples

```
data(LL)

todrop <- c("treated","re78")

imbalance(LL$treated, LL, drop=todrop)

# cem match: automatic bin choice
mat <- cem(treatment="treated", data=LL, drop="re78")</pre>
```

4.5 k2k: Reduction to k2k Matching

Description

Reduces a CEM output to a k2k matching

Usage

```
k2k(obj, data, method=NULL, mpower=2, verbose=0)
```

Arguments

obj an object as output from cem

data the original data.frame used by cem

method distance method to use in k2k matching. See Details.

mpower power of the Minkowski distance. See Details.

verbose controls level of verbosity. Default=0.

Details

This function transforms a typical cem matching solution to a k-to-k match, with k variable along strata: i.e., in each stratum generated by cem, the match is reduce to have the same number of treated and control units. (This option will delete some data that matched well, and thus likely increase the variance, but it means that subsequent analyses do not require weights.)

The user can choose a method (between 'euclidean', 'maximum', 'manhattan', 'canberra', 'binary' and 'minkowski') for nearest neighbor matching inside each cem strata. By default method is set to 'NULL', which means random matching inside cem strata. For the Minkowski distance the power can be specified via the argument mpower'. For more information on method != NULL, refer to dist help page.

After k2k the weights of each matched observation are set to unity.

Value

obj an object of class cem.match

Author(s)

Stefano Iacus, Gary King, and Giuseppe Porro

References

Stefano Iacus, Gary King, Giuseppe Porro, "Matching for Casual Inference Without Balance Checking," http://gking.harvard.edu/files/abs/cem-abs.shtml

Examples

```
data(LL)

# cem match: automatic bin choice
mat <- cem(treatment="treated", data=LL, drop="re78")
mat
mat$k2k

# ATT estimate
att(mat, re78 ~ treated, data=LL)

# transform the match into k2k
mat2 <- k2k(mat, LL, "euclidean", 1)
mat2
mat2$k2k

# ATT estimate after k2k
att(mat2, re78 ~ treated, data=LL)</pre>
```

4.6 L1.meas: Evaluates L1 distance between multidimensional histograms

Description

Evaluates L1 distance between multidimensional histograms

Usage

L1.meas(group, data, drop=NULL, breaks = NULL, weights)

Arguments

group the group variable

data the data

drop a vector of variable names in the data frame to ignore

breaks a list of vectors of cutpoints; if not specified, automatic choice will be

made

weights weights

Details

This function calculates the L1 distance on the k-dimensional histogram.

If breaks is not specified, the Scott automated bin calculation is used (which coarsens less than Sturges, which used in cem). Please refer to cem help page. In this case, breaks are used to calculate the L1 measure.

If breaks is missing, the default rule to calculate cutpoints is the Scott's rule.

Value

An object of class L1.meas which is a list with the following fields

breaks A list of cutpoints used to calculate the L1 measure

value The numerical value of the L1 measure

Author(s)

Stefano Iacus, Gary King, and Giuseppe Porro

References

Stefano Iacus, Gary King, Giuseppe Porro, "Matching for Casual Inference Without Balance Checking," http://gking.harvard.edu/files/abs/cem-abs.shtml

Examples

```
data(LL)
L1.meas(LL$treated,LL, drop=c("treated","re78"))
```

4.7 LL: Lalonde dataset

Description

Lalonde experimental dataset (see cited reference).

Usage

```
data(LL)
```

Format

A data frame with 722 observations on the following 10 variables.

```
treated treatment variable indicator
```

age age

education years of education

black race indicator variable

married marital status indicator variable

nodegree indicator variable for not possessing a degree

re74 real earnings in 1974

re75 real earnings in 1975

re78 real earnings in 1978 (post-treatment outcome)

hispanic ethnic indicator variable

u74 unemployment in 1974 indicator variable

u75 unemployment in 1975 indicator variable

Source

see references

References

4.8 LeLonde: Modified Lalonde dataset

Description

This is a modified version of the Lalonde experimental dataset used for explanatory reasons only.

Usage

data(LL)

Format

A data frame with 722 observations on the following 11 variables.

```
treated treatment variable indicator
age age
education years of education
black race indicator variable
married marital status indicator variable
nodegree indicator variable for not possessing a degree
re74 real earnings in 1974
re75 real earnings in 1975
re78 real earnings in 1978 (post-treatment outcome)
hispanic ethnic indicator variable
u74 unemployment in 1974 indicator variable
```

u75 unemployment in 1975 indicator variable

q1 answer to survey question n1

Details

This data is a copy of the original Lalonde (1986) data set (see LL) with 10% of missing data and an additional variable q1 which is the fictituous answer to the questionarie on "Agreement on this job training program".

Source

see references

4.9 relax.cem: Diagnostic tool for CEM

Description

Diagnostic tools for CEM

Usage

```
relax.cem(obj, data, depth=1, verbose = 1, L1.breaks=NULL, plot=TRUE, fixed=NULL,
    shifts=NULL, minimal=NULL, use.coarsened=TRUE, ...)
relax.plot(tab, group="1", max.terms=50, perc=.5, unique=FALSE, colors=TRUE)
```

Arguments

obj an object of class cem.

data the original data.

verbose controls the level of verbosity.

L1.breaks list of cutpoints for the calculation of the L1 measure.

plot plot the solutions?

tab the output table from relax.cem.

fixed vector of variable names which will not be relaxed.

max.terms plot only the last best results of relax.cem.

shifts a vector of proportions of shifts.

minimal the minimal number of intervals acceptable after relaxation. Should be a

nameed list of positive integers.

group character string denoting group id. Defaults to "1".

perc only plot if percentage of matched units is greater than perc.

unique only plot different solutions (in terms of matched units).

depth if 1, relaxes up to dropping one var, if 2 relaxes (up to dropping) two vars,

etc.

use.coarsened

used coarsened values for continuous variables.

colors If TRUE each variable is plotted in a different colour.

... passed to the relax.plot function.

Details

relax.cem starts from a cem solution (as given by cem) and tries several relaxed coarsenings on the variables. Coarsenings corresponds to dividing the support of each variable into a decreasing number of intervals of the same length (even if in the starting solution intervals are of different lengths). Because CEM is MIB, the number of matched units increases as the number of intervals decrease. All variables are coarsened into k intervals along a sequence which starts from the original number of intervals and decreases to 10 intervals by 2, then continues from 10 down to 1 intervals by 1. If minimal is specified, variables are coarsened down to that minimal value.

To observe MIB property of CEM use.coarsened (default) should be set to TRUE; otherwise the coarsening of the continuous variable will be recalculated at each iteration and there is no guarantee of monotonicity.

relax.cem outputs a list of tables. Each table is named Ggroup where group is the id of the group. Each Ggroup table is ordered in increasing order of matched units of group group. Columns PercGgroup and Ggroup report percentage and absolute number of matched units for each group. Column Relaxed indicates which relaxation has been done, with something like "V1(4), V3(5)", which means "variable V1 has been split in 4 intervals of the same length and variable V3 into five intervals". Thus, the number of intervals is reported in parenthases and if equal to 1 means that the corresponding variable is excluded from affecting the match (i.e. all observations are assigned to the same interval).

If shifts is not null, each coarsening is shifted accordingly (see shift.cem for additional details). In case of shifting "S:" appears in the labels.

The relax.plot, plot all the different relaxation in increasing order of number of treated units matched. For each coarsening it also reports the value of the L1 measure. The table generated by relax.cem may contain many entries. By default, only a portion of best coarsenings are plotted (option max.terms). In addition, the user can specify to plot the corasening for which at least a certain percentage of treated units have been matched (option perc, by default 50 In addition, of several different coarsenings which lead to the same number of treated units matched, the user can specify to plot only one of them using the option unique = TRUE (default).

If L1.breaks are NULL they are taken from the cem object if available or calculated atumatically as in cem.

Calling directly plot on the output of cem.relax has the same effect of calling directly relax.plot.

Value

tab an invisible object containing the tabs and the L1breaks used

# uncomment to run. Might be slow
# tab4 <- relax.cem(mat, LL, depth=2, minimal=list(age=4, education=3,re75=6), plot=FALSE,
# relax.plot(tab4)
# relax.plot(tab4, unique=TRUE)
# relax.plot(tab4, perc=0.7)
```

4.10 shift.cem: Diagnostic tool for CEM

Description

Diagnostic tools for CEM. Applies leftward and rightward shifts of the cutpoints.

Usage

```
shift.cem(obj, data, shifts=NULL, verbose=0, plot=TRUE)
```

Arguments

obj and object of class cem

data the original data

shifts a vector of proportions of shifts
verbose controls the level of verbosity

plot whether to plot a graphic representation of the search

Details

For each variable, shift all the cutpoints left and right by shifts times the smallest epsilon of the coarsening. Shifting to the right produces a new cell on the left; shift to the left, adds a new cell to the coarsening on the right. Only positive proportions should be used; the algorithm will produce shifting on the left or on the right. The best shifting of the original cem match is produced as output, where best is defined in terms of the maximal total number of matched units mT+mC (see below).

By default, the function returns minimal information about the execution of the algorithm. By setting a value greater than 0 in option verbose more feedback on the process is returned.

Option plot = TRUE plots the number of treated units matched mT, the number of control units matched mC, and the sum mT+mC, as a function of the shifts.

Value

tab an invisible object containing a new cem object
